Diffuse idiopathic skeletal hyperostosis (DISH) is a disease characterized by massive, non-inflammatory ossification with intensive formation of osteophytes affecting ligaments, tendons and fascia of the anterior part of the spinal column mostly in the middle and lower thoracic regions. However, isolated and predominant cervical spinal involvement may occur. It has predilection for men (65%) over 50 years of age and a prevalence of approximately 15-20% in elderly patients.1 A CT scan is one of the diagnostic tools. The radiographic diagnostic criteria in the spine include: 1) osseous bridging along the anterolateral aspect of at least four vertebral bodies; 2) relative sparing of intervertebral disc heights with minimal or absent disc degeneration; and 3) absence of apophyseal joint ankylosis and sacroiliac sclerosis.2 We present a rare case of dysphagia over two years duration due to DISH.

CASE REPORT
A 55-year-old Malay man presented with intermittent dysphagia for two years duration. He denied foreign body ingestion, globus sensation or any laryngeal trauma, shortness of breath, hoarseness or any neurological deficits. A solitary smooth mass on the right posterolateral pharyngeal wall that was hard in consistency was appreciated on oropharyngeal examination. (Figure 1) There was no significant cervical lymphadenopathy and the neurological examination was unremarkable. Cervical Radiographs and CT scan showed marked ossification at the right anterolateral aspect of cervical vertebral bodies C2 to C7 most probably representing a Diffuse Idiopathic Skeletal Hyperostosis. (Figures 2, 3) He was treated conservatively with 6-monthly follow up.

DISCUSSION
Diffuse Idiopathic Skeletal Hyperostosis (DISH) is an ossifying diasthesis characterized by the thickening and calcification of soft tissue (ligaments, tendons and joint capsule) resulting in secondary formation of osteophytes. Most commonly it affects the paraspinal ligaments, predominantly the anterior longitudinal ligament and occasionally the posterior longitudinal ligament.2 It was first described as senile ankylosing hyperostosis of the spine by Forestier and Rodes Querol in 1950.3 In 1970 Resnick et al. coined the term DISH for this systemic entity. Radiologically, they established 3-diagnostic criteria which include: 1) Presence of flowing
ossification of anterior longitudinal ligament of at least four contiguous vertebral bodies; 2) Preservation of intervertebral disc height; and 3) Absence of apophyseal joint ankylosis or sacroiliac joint erosion, sclerosis or fusion.⁴

Cervical anterior osteophytes accompanying DISH are mostly asymptomatic. They may present with cervical pain and stiffness. Large osteophytes however do cause dysphagia and it is the most common presenting complaint, affecting 17 – 28% of patients.⁵ Many different mechanisms have been suggested as the cause of the dysphagia including mass effect on the esophagus by the osteophytes and neuropathy due to recurrent laryngeal nerve impingement.⁵,⁶ According to Lin et al., in addition to distortion of laryngoesophageal anatomy and functions, osteophytes of cervical vertebrae can alter the mechanics of pharyngeal swallowing leading to secondary inflammation and edema of mucosa and soft tissue.⁶ Although airway symptoms in patients with DISH appear to be rare, clinicians should be aware of this condition and its potential for acute respiratory complications.

The etiology of DISH is still unclear, however according to Calisanelle et al. it may be associated with excessive mechanical stress, hyperlipidaemia, increased levels of insulin with or without diabetes mellitus, increased levels of insulin-like growth factor-1 and hyperuricaemia.⁷ A positive HLA–B8 has also been reported and hypervascularity may also play a role in the etiopathogenesis of DISH.⁷,⁸,⁹

Differential diagnosis of DISH includes ankylosing spondylitis, spondylosis deformans, osteoarthritis and esophageal malignancies where it should be considered when the dysphagia cannot be explained by small anterior osteophytes.⁵
FEATURED GRAND ROUNDS

Treatment can be divided into conservative treatment with dietary modification, swallowing therapy sessions and analgesia for early stages of mild dysphagia. Chiropractic treatment and acupuncture are popular alternatives among patients. The benefit of chiropractic therapy may lie in its role in increasing range of movement of the spine and providing pain relief. When conservative treatment fails, surgical interventions such as osteophytectomy, tracheotomy and feeding tube insertion are indicated. Surgical excision via perioral transpharyngeal route for C1 and C2 vertebrae or anterior cervical approach for C3 to C7 vertebrae is preferred. The aim of the surgery is to provide satisfactory decompression of the esophagus. Recent studies have shown that patients treated surgically with osteophytectomy had marked improvement if not complete resolution of their upper aerodigestive disturbances. It should be remembered that surgical interventions harbor the risk of recurrent laryngeal nerve injury, Horner’s syndrome, cervical instability, persistent symptoms and recurrence. Dysphagia caused by diffuse idiopathic skeletal hyperostosis is an uncommon entity. Radiological evaluation specifically CT scans are diagnostic and can rule out other possible causes of oropharyngeal mass. Surgical decompression may relieve the dysphagia when conservative treatments fail.
